B$^{\bowtie}$Tree

A mechanism to drive existing B^{+}Trees to do Join Internally.

RDBMS challenges

Performance has been always a challenge for relational databases. A major problem with relational database that a good schema requires many tables in relation between them, and in consequence the calculation of many joins to satisfy the queries.

DBA spends lots of time to tune the database. Some database schemas are not in BCNF just to avoid some joins. Also some materialized views are just to avoid it. Star Schema born from the fact that joining is complex and to simplify joins.

Standard indexes

The standard indexes used in relational databases are B+tree, hashed keys and bitmap indexes but the problem all suffers from some restrictions.

B+tree have among others the fact that it work just on one table.

Hashed keys are very fast but they require a full key lookup, a perfect match, and a unique identifying value.

Bitmap is also good but it has a limit on the number of different values a column can have.

Bitmap Join Index & Materialized Views

Bitmap join index is efficient but is not general; it is based on Star Schema. Has a lots of bitmap arrays depending on the size of the dimensions tables.

Materialized Views are redundant. No one use Materialized View to order a table, because index is the more natural way. Also B⋈Tree index is the more natural way to get the join.

B⋈TREE Overview

B⋈tree is a new index technology that is based on B$^+$tree that pre-join the tables inside it.

B⋈tree uses "Virtual Tables" and "Join Path Lists" to make pre-join internally, so it doesn't use the multidimensional index technique with the benefit of more easier and more concise algorithm, no limit for the number of tables in join and easy use: the same way as a native B$^+$tree.

Given n Tables in join, scanning the B⋈tree return a set of pointers for the rows in join for any possible combination of tables in join.

B⋈TREE Index

To understand how B⋈TREE Index works let see what happens when we insert a new Row R_m from Table T_i into the database.

Suppose that table T_i is in Direct Join with a table T_k, we have to look for all the Rows $R_n \ldots R_z$ in T_k that satisfy the join condition with R_m and insert Rows references to $R_m R_{n....}$ $R_m R_z$ in the virtual table T_{ik}.

The process should be repeated for $R_m R_{n....}$ $R_m R_z$ with a table in join at least with one of the base tables constituting the Virtual Join Table T_{ij} and so on until we scan a path in the sequence of tables in join.

Transformation of Existing B^+Tree

- The internal definition for the creation of a B^+Tree take in consideration the following:
  - Name of B^+Tree index follow by an index
  - Number of base tables constituting the virtual table indexed by the B^+Tree
  - Length and type of Keys
  - Length and type of Inherited Keys (They are supplementary fields inserted in the B^+Tree but they are not part of the key and they are not used for comparison)

- Declare the page of B^+Tree as a buffer of bytes and divide it as needed. Many existing B^+Tree follow this technique to support different type of multiple columns Key.

- The Leaf Page structure consists of:
  - Pointer to the previous sibling page
  - number of elements in which everyone consists of:
    - Space for the columns forming the keys
    - Space for the Data Pointers (Row Ids) to reference the Row in every table
    - Space for the columns forming the Inherited Keys
  - Pointer to the next sibling Page

Transformation of Existing B^+Tree (continue)

- The Non Leaf Page structure consists of:
  - Pointer to a child page which key values are smaller than all the keys in the page
  - number of elements in which everyone consists of:
    - Space for the columns forming the keys
    - Pointer to a child page which key values are bigger than the keys in the Element

- Due to the fact that many join keys are duplicates, change has been made for the duplicates in the sense when 2 keys are equals, we consider the data references for them. The B^+Tree keeps these possibly duplicated keys separate internally by combining the unique sequence of data references with each key. The process of combination is done logically, and requires no additional space for key storage.

Many advanced B^+Tree in the market use (Key, Data Reference) combination to refer to unique Row eliminating duplicates internally and use additional fields others than the one forming the key to avoid access to the table.

So for those B^+Trees, the only modification is instead of space of one Data Reference is a space for multiple Data Reference Space.

Definitions

- Base Table:

  Base tables are database objects whose structure and the data they contain are both on disk.

- Virtual Table:

  Virtual tables are tables whose contents are derived from base tables. Only its definition (base tables Names constituting it) is stored on disk.

Definitions

Direct Join:

Two tables are in Direct Join if there is a link between them (in other sense if there is common columns between them).

Join Graph:

A graph representing direct join between tables.

Adjacency List:

List for every table T_i in the database all those tables in direct Join with it.

Generating Join Graph

- **Base Tables represent the vertexes of the Join Graph.**
- **Due to the fact that join is commutative, for every pair of tables in direct join between them as defined by DBA create an undirected edge to link them.**
- **It is very easy to knows which tables are in direct join with others tables from the definition of common columns between them.**

The algorithm for generating the Linked List representation of the join Graph is the following:

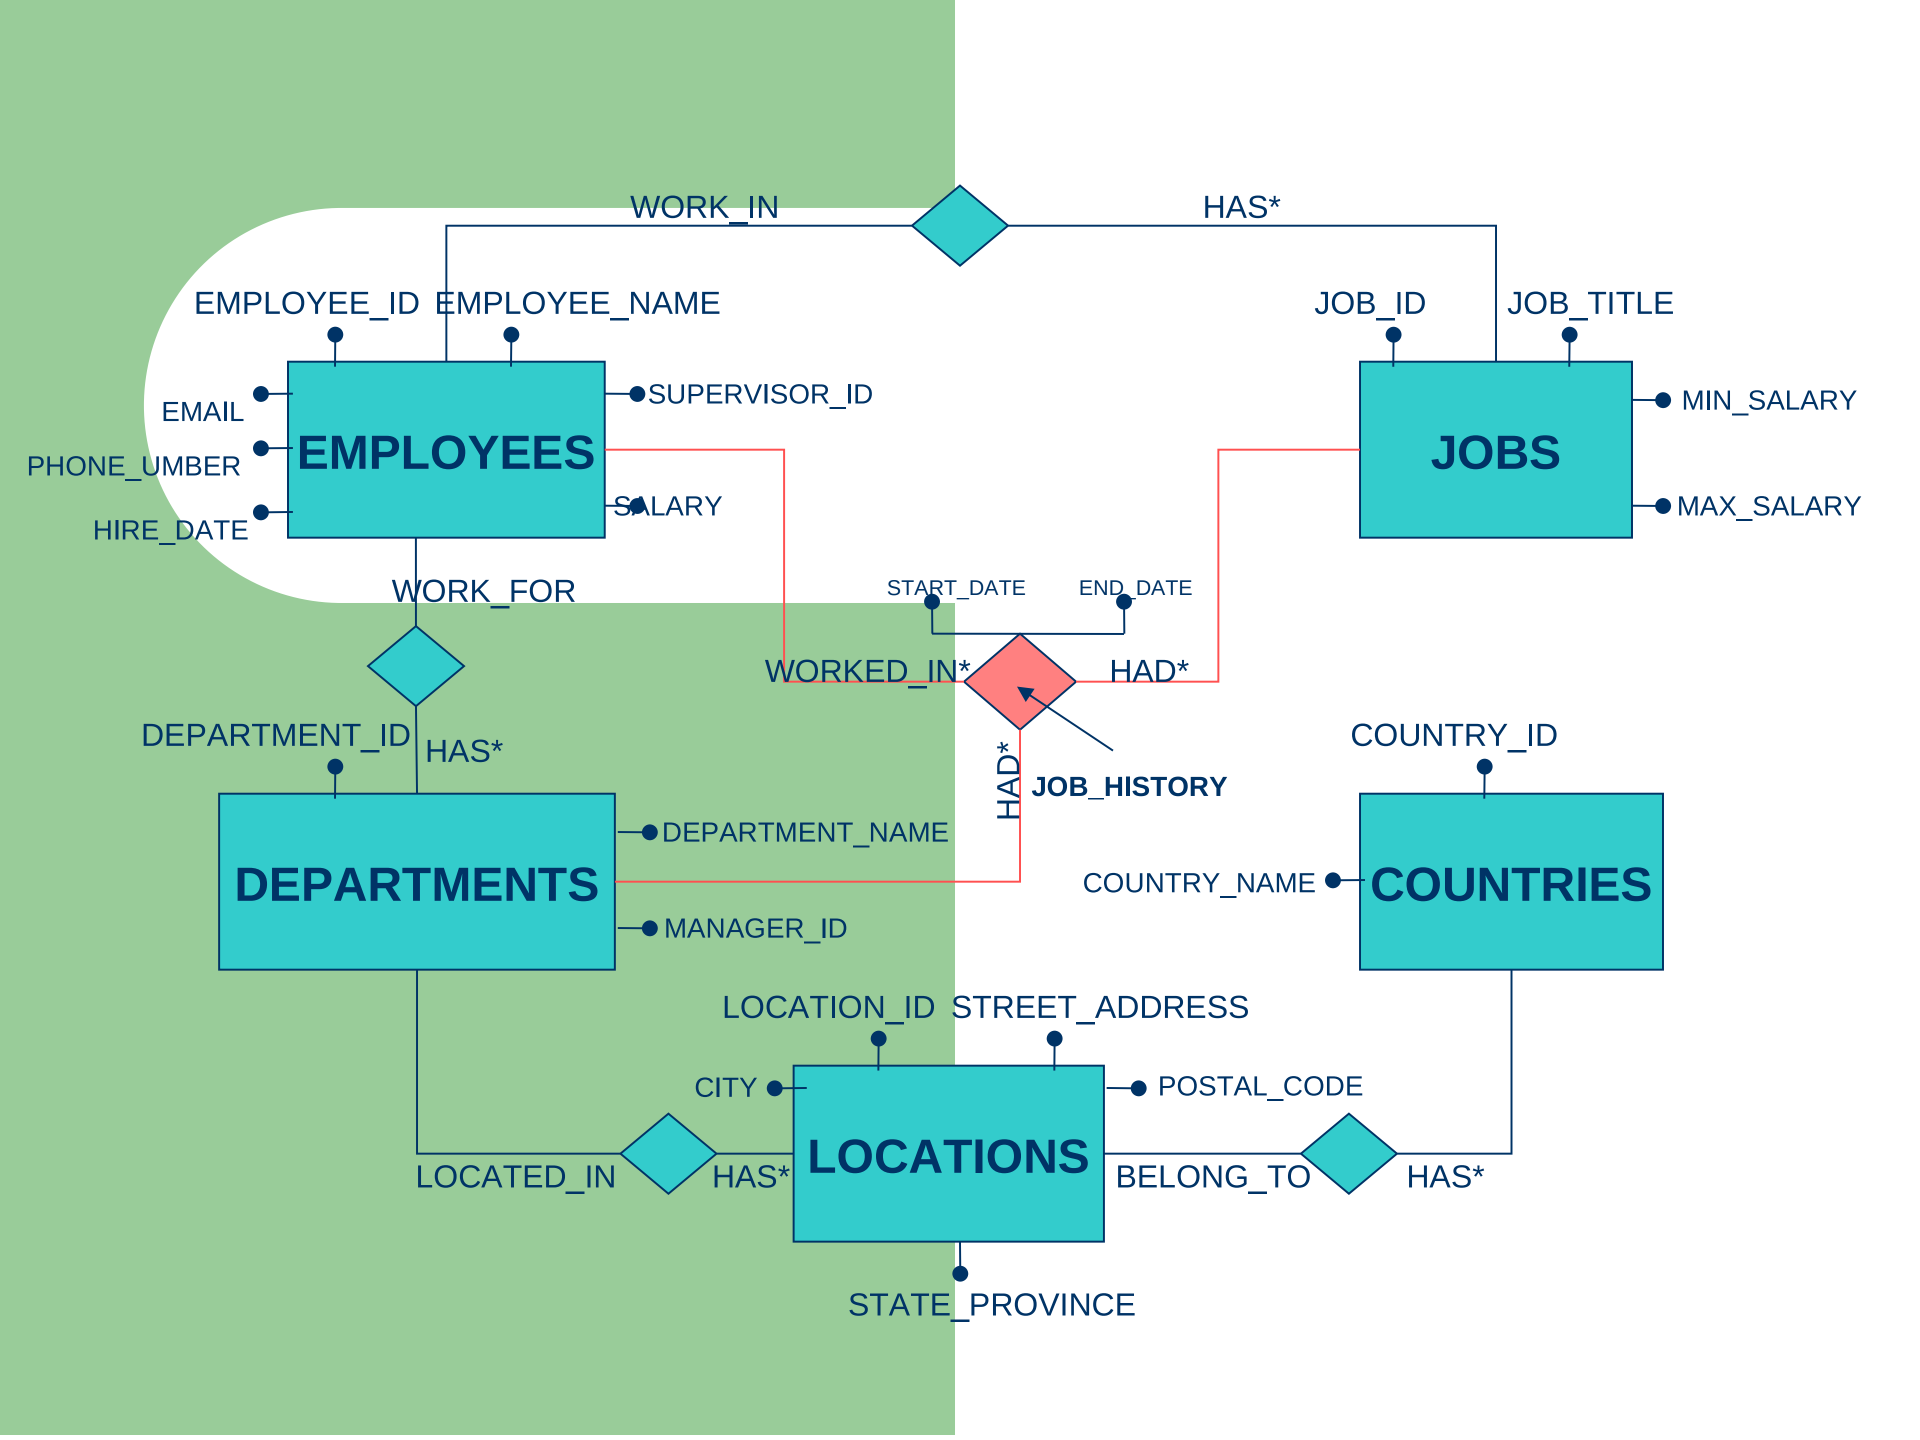
<u>generateJoinGraph (in BaseTables; out JoinGraph)</u>

insert the base tables as vertexes of the graph

for every direct join between 2 tables T_i and T_k where T_i is the table of order i and T_k is the table of order k as defined by the DBA do

AdjacentList[T_i] += T_k follow by the common key

AdjacentList[T_k] += T_i follow by the common key



WORK_IN
HAS*
EMPLOYEE_ID
EMPLOYEE_NAME
JOB_ID
JOB_TITLE
EMAIL
SUPERVISOR_ID
EMPLOYEES
JOBS
MIN_SALARY
PHONE_UMBER
SALARY
MAX_SALARY
HIRE_DATE
WORK_FOR
START_DATE
END_DATE
WORKED_IN*
HAD*
DEPARTMENT_ID
HAS*
COUNTRY_ID
HAD*
JOB_HISTORY
DEPARTMENT_NAME
DEPARTMENTS
COUNTRY_NAME
COUNTRIES
MANAGER_ID
LOCATION_ID
STREET_ADDRESS
CITY
POSTAL_CODE
LOCATIONS
LOCATED_IN
HAS*
BELONG_TO
HAS*
STATE_PROVINCE

Transforming the entity relationship schema into the relational model, we get the following tables:

```
CREATE TABLE EMPLOYEES
 (
    EMPLOYEE_ID INT NOT NULL,
    EMPLOYEE_NAME VARCHAR(35),
    EMAIL VARCHAR(25),
    PHONE_NUMBER VARCHAR(20),
    HIRE_DATE DATE,
    SUPERVISOR_ID INT NOT NULL,
    JOB_ID VARCHAR(10),
    SALARY NUMERIC(8,2),
    DEPARTMENT_ID VARCHAR(3)
 );
CREATE TABLE JOB_HISTORY
 (
     EMPLOYEE_ID INT,
     START_DATE DATE,
     END_DATE DATE,
     DEPARTMENT_ID VARCHAR(3),
     JOB_ID VARCHAR(10)
 );
CREATE TABLE JOBS
 (
    JOB_ID VARCHAR(10),
    JOB_TITLE VARCHAR(35),
    MIN_SALARY DOUBLE,
     MAX_SALARY DOUBLE
 );
```

```
CREATE TABLE DEPARTMENTS
 (
    DEPARTMENT_ID VARCHAR(3),
    DEPARTMENT_NAME VARCHAR(30),
    MANAGER_ID INT,
    LOCATION_ID INT
  );
CREATE TABLE LOCATIONS
 (
    LOCATION_ID INT,
    STREET_ADDRESS VARCHAR(40),
    POSTAL_CODE VARCHAR(12),
    CITY VARCHAR(30),
    STATE_PROVINCE VARCHAR(25),
    COUNTRY_ID CHAR(2)
);
CREATE TABLE COUNTRIES
 (
    COUNTRY_ID CHAR(2),
    COUNTRY_NAME VARCHAR(40)
 );
```

The join for the example is the following:

List where every employee have been worked before along with the department that he is working now:

```
CREATE JOIN INDEX RECENT_IDX
  ON            EMPLOYEES(LAST_NAME), DEPARTMENTS, JOBS, JOB_HISTORY, LOCATIONS, COUNTRIES
  WHERE   EMPLOYEES.EMPLOYEE_ID = JOB_HISTORY.EMPLOYEE_ID
    AND   JOBS.JOB_ID = JOB_HISTORY.JOB_ID
    AND   EMPLOYEES.DEPARTMENT_ID = DEPARTMENTS.DEPARTMENT_ID
    AND   DEPARTMENTS.LOCATION_ID = LOCATIONS.LOCATION_ID
    AND   LOCATIONS.COUNTRY_ID = COUNTRIES.COUNTRY_ID;

SELECT EMPLOYEES.EMPLOYEE_NAME,
       JOBS.JOB_TITLE AS JOB_TITLE,
       DEPARTMENTS.DEPARTMENT_NAME AS DEPARTMENT_NAME,
       COUNTRIES.COUNTRY_NAME AS COUNTRY_NAME
  FROM   EMPLOYEES, JOB_HISTORY, DEPARTMENTS,
         LOCATIONS, JOBS, COUNTRIES
  WHERE   EMPLOYEES.EMPLOYEE_ID = JOB_HISTORY.EMPLOYEE_ID
    AND   JOBS.JOB_ID = JOB_HISTORY.JOB_ID
    AND   EMPLOYEES.DEPARTMENT_ID = DEPARTMENTS.DEPARTMENT_ID
    AND   DEPARTMENTS.LOCATION_ID = LOCATIONS.LOCATION_ID
    AND   LOCATIONS.COUNTRY_ID = COUNTRIES.COUNTRY_ID;
```

This is another join on the same tables:

List where every employee have been worked before along with the department that he is working before:

```
CREATE JOIN INDEX HISTORY_IDX
 ON       EMPLOYEES(LAST_NAME), DEPARTMENTS, JOBS, JOB_HISTORY, LOCATIONS, COUNTRIES
 WHERE  EMPLOYEES.EMPLOYEE_ID = JOB_HISTORY.EMPLOYEE_ID
  AND  JOBS.JOB_ID = JOB_HISTORY.JOB_ID
  AND  JOB_HISTORY.DEPARTMENT_ID = DEPARTMENTS.DEPARTMENT_ID
  AND  DEPARTMENTS.LOCATION_ID = LOCATIONS.LOCATION_ID
  AND  LOCATIONS.COUNTRY_ID = COUNTRIES.COUNTRY_ID;

SELECT EMPLOYEES.FIRST_NAME +
    EMPLOYEES.LAST_NAME AS NAME,
    JOBS.JOB_TITLE AS JOB_TITLE,
    DEPARTMENTS.DEPARTMENT_NAME AS DEPARTMENT_NAME,
    COUNTRIES.COUNTRY_NAME AS COUNTRY_NAME
 FROM  JOB_HISTORY, DEPARTMENTS,
     LOCATIONS, JOBS, COUNTRIES, EMPLOYEES
 WHERE  EMPLOYEES.EMPLOYEE_ID = JOB_HISTORY.EMPLOYEE_ID
  AND  JOBS.JOB_ID = JOB_HISTORY.JOB_ID
  AND  JOB_HISTORY.DEPARTMENT_ID = DEPARTMENTS.DEPARTMENT_ID
  AND  DEPARTMENTS.LOCATION_ID = LOCATIONS.LOCATION_ID
  AND  LOCATIONS.COUNTRY_ID = COUNTRIES.COUNTRY_ID;
```

generateJoinGraph (in BaseTables; out JoinGraph)

insert the base tables as vertexes of the graph

for every direct join between 2 tables of the form T_i and T_k where T_i is the table of order i and T_k is the table of order k as defined by the DBA do

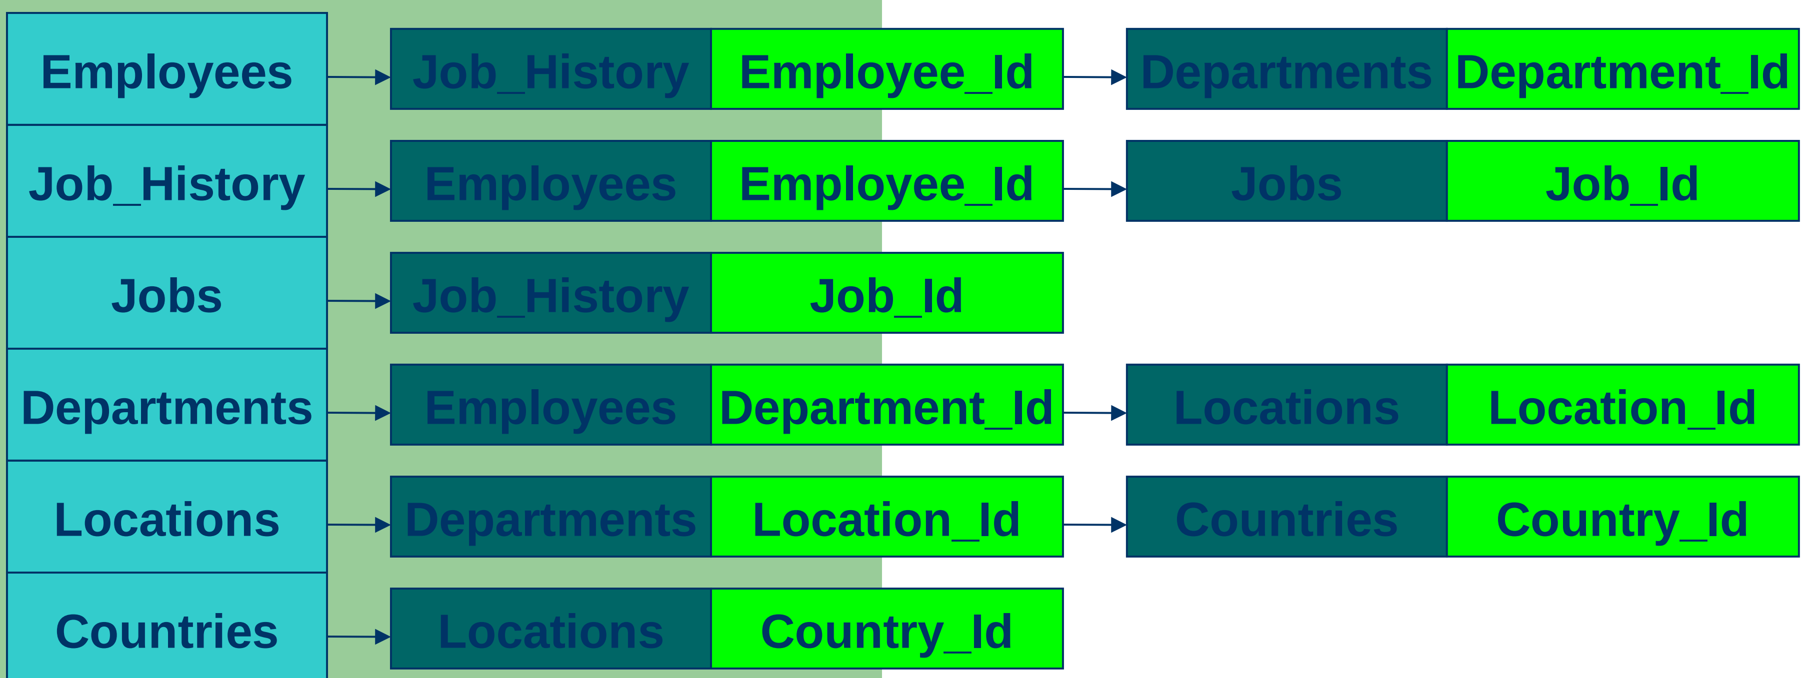
Join Graph

Linked List representation of the Join Graph



Adjacency List

Definitions

Join Path List:

A sequence of tables $T_0 \ldots T_{n-1}$ is in the Join Path List if every T_i of them is at least in direct join with another table in the sequence.

Notation

- When index i is not between brackets like in T_i, it represent a base table T_i.
- When index i is between brackets like in $T_{[i]}$, it represent a base table T_i or a virtual table in which index i represent a set of indexes for the base tables forming the virtual table.

Steps to generate function: Key($T_{[j]}$)

getFirstAdjacentListKey($T_{[j]}$, $T_{[k]}$)

for every Base Table T_l in $T_{[j]}$ do

Take one at a time

for every $T_{Link(l)}$ do

Take one at a time

if $T_{Link(l)}$ in $T_{[k]}$ then

return(key(T_l,$T_{Link(l)}$))

Normally one of the 2 tables $T_{[j]}$ or $T_{[k]}$ is a base table this is why we stop after founding the key.

Key could be a one column key or multicolumn key that satisfy the join condition.

Steps to generate Join Path List for the join sequence $T_0 \ldots T_m$

let $T_0 \ldots T_m$ be the base tables

create 2 dynamic arrays queue and path

insert T_0 into path

insert T_0 into queue

repeat

    $T_{Element}$ = First Table in queue

    for every Link Item in Adjacent Link of $T_{Element}$ from the Join Graph do

        if the Link Item is in the join sequence then

            if path doesn't contain the Link Item then

                insert Link Item into path

                insert Link Item into queue

    remove $T_{Element}$ from queue

until queue is empty

Steps to generate Join Path List for the join sequence $T_0 \ldots T_m$ (continue)

insert all the names of base tables from path as vertexes in the JoinPathList

create a local buffer buf

insert into buf the first entry from path

for all the remainder entries in path do

- **take one T_i at a time**
- **PathJoinAdjacentList(T_i) = $T_{[buf]}$**
- **Key(T_i) = getFirstAdjacentListKey(T_i,$T_{[buf]}$)**
- **PathJoinAdjacentList($T_{[buf]}$) = T_i**
- **Key($T_{[buf]}$) = getFirstAdjacentListKey ($T_{[buf]}$,T_i)**
- **$T_{[buf]}$ + = T_i**
- **Insert NodesList[$T_{[buf]}$] = $T_{[buf]}$**

Steps to generate Join Path List for the join sequence $T_0 \ldots T_m$ (continue)

create a structure buf with 2 fields: Table and Key

for all the tables in JoinPathList going downward do

take one $T_{[i]}$ at a time

for all Base Tables in $T_{[i]}$ do

take one T_k at a time

for every buf.Table = T_k do

if (buf.key != Key($T_{[i]}$)) and (buf.Key not in InheritedKey($T_{[i]}$)) then
InheritedKey($T_{[i]}$) += buf.key

if T_l is the table from which comes Key($T_{[i]}$) then

buf.Table = T_l

buf.key = Key($T_{[i]}$)

```
generateJoinPathList (in Join Base Tables, JoinGraph; out JoinPathList)
let T0…Tm be the base tables
create 2 dynamic arrays queue and path
insert T0 into path
insert T0 into queue

Join Path List
Adjacent List

Suppose we wants the join sequence of the tables ordered by Employees.Name and Departments.Department_Id, applying the algorithm, the JoinPathList becomes:

Join Path List

	NodesList	Adjacent Table	Table	Key	Inherited Table	Key
0	Employees	Job_History	Employees	Employee_Id	Employees	Name
					Employees	Department_Id
1	Job_History	Employees	Job_History	Employee_Id	Job_History	Job_Id

Create B^+Trees

- The Nodes (Vertexes) in the JoinPathList represents all the base tables + virtual tables constituting from the base tables by adding one at a time in mode that the one added is at least in direct join with its precedents.
- Defining a B^+Tree for every node, the ones for the virtual tables have for every key a set of data pointers equal to the number of base tables constituting it and from definition of the virtual tables, combining the rows pointed by those data pointers we obtain a joined row.

The algorithm for creating B^+Trees is the following:

```
create B+Trees(in PathJoinList; out B+Trees);
give a general name for the BJoinTree
for all entries in JoinPathList do
        take one node at a time
        create a B+Tree for the node defined as
                name of the B+Tree equal to the name of BJoinTree follow by the
                   index number of the node entry
                Number of data pointers equal to the number of base tables
                   constituting the virtual table of the node
                Key is defined by the pair <Table, Key> in the adjacent list of the
                   node
                Inherited Keys are defined by the pairs <Table, Inheritred Key> in
                   the adjacent list of the node
```

Give a general name for the $B^{\bowtie}$Tree.

Give for every entry in the JoinPathList a B^{+}Tree index with name as the $B^{\bowtie}$Tree + the PathJoinList entry number.

About the last virtual table, it index has no keys, it works because we consider pairs of < keys, Data Pointers > as key, so they are ordered by their data pointers. Scanning the index we get all the sequences of joined data pointers.

Non Terminal has repeated empty keys they point to different pages.

Duplicate keys are inserted and when a page is full , the key is repeated in the non terminal.

In any case we can incorporate any key of our choice from the tables forming the virtual table.

If the table is in join with itself, consider the table twice as aliases.

Implementation:

Use a big buffer and from the Data Dictionary divide it by the keys length, inherited keys length and space for the number of Data Pointers.

The $B^{\bowtie}$Tree is formed from (2*n-1) indexes.

We can use one index that include all these indexes by including an index number and treated like a key., so instead of <keys, Data Pointers> treated as a Key, we use <Index PathJoinList enty number, Keys, Data Pointers> as a key.

IMPORTANT NOTE

The data pointers to the tables in join are in order with the Base Tables of the last Virtual Table and not as declared in the create constructor, this is due to the fact that Path is not always in the same order as the tables declared in the constructor.

So to know the order of data pointers in respect to the tables in join, the property “BaseTables” in “BjoinTreeU.pas” should be called to get it.

The function GetDataRefByTableName(BaseTable: string; DataRef: array of DataPointerType): DataPointerType; give the data reference to the row in base table. See Test Index (Button5) in SQLProject.

Insert routine

When a new row R_m from table T_i get inserted do the following:

– Locate the entry of T_i in the JoinPathList

– From its adjacent List, locate the definition of the keys and inherited keys

– From Row R_m get the columns constituting the keys and the inherited keys

– Call AddJoinKey (T_i, Keys, InheritedKeys, DP_i) where DP_i is the row id of row R_m.

Notice that $Keys_i$, $InheritedKeys_i$ and DP_i are relative to the row R_m from table T_i

AddJoinKey ($T_{[i]}$, [DP_i])

- Call AddKey ($B^+Tree(T_{[i]})$, $keys_{[i]}$, $InheritedKeys_{[i]}$, [DP_i]) for the index of table $T_{[i]}$
- Locate the entry of $T_{[i]}$ in the JoinPathList
- From its adjacent List, locate the Table $T_{[k]}$ adjacent to it and do the following:
  - Locate the entry of $T_{[k]}$ in the JoinPathList
  - FindKey($B^+Tree(T_{[k]})$, $Keys_{[i]}$)
  - While found(keys[i]) do

    ReturnKeys($B^+Tree(T_{[k]})$, $keys_{[k]}$, $InheritedKeys_{[k]}$, [DP_k])

    Locate the entry of $T_{[ik]}$ in the JoinPathList

    From its adjacent List, locate the definition of the keys and inherited keys

    From $keys_{[i],}$ $inheritedkeys_{[i]}$, $keys_{[k],}$ $inheritedkeys_{[k]}$ get the keys and inherited keys of $T_{[ik]}$

    AddJoinKey ($T_{[ik]}$, $Keys_{[ik]}$, $InheritedKeys_{[ik]}$, [DP_{ik}])

    NextKey($B^+Tree(T_{[k]})$, $Keys_{[i]}$)

AddJoinKey ($T_{[i]}$, [DP_i])

In the same fashion when using an ordinary B^+Tree and one row get inserted, so we check the definition of the B^+Tree to get the necessary keys from the row to insert them, with B^{Join}Tree we check the definition to get the keys and the inherited keys.

Call AddjoinKey(T_i,[keys],[DP_i])

As we can notice from the last index we have an element with 6 data pointers respectively pointing to the 6 base tables forming the virtual table T_{10}, with all values equal to the first row on each table, those rows are in join together.

Inserting all the remaining rows from the tables we obtain the following indexes where the last index shows the join between the rows from the tables.

B+Tree(T_0)

Delete routine

When a row R_m from table T_i get deleted do the following:

- Locate the entry of T_i in the JoinPathList
- From its adjacent List, locate the definition of the keys and inherited keys
- From Row R_m get the columns constituting the keys and the inherited keys
- Call DelJoinKey (T_i, $Keys_i$, $InheritedKeys_i$, DP_i) where DP_i is the row id of row R_m

  Notice that $Keys_i$, $InheritedKeys_i$ and DP_i are relative to the row R_m from table T_i

DelJoinKey ($T_{[i]}$, $Keys_{[i]}$, $InheritedKeys_{[i]}$,[DP_i])

- Call delKey ($B^+Tree(T_{[i]})$, $keys_{[i]}$, $InheritedKeys_{[i]}$, [DP_i]) for the index of table $T_{[i]}$
- Locate the entry of $T_{[i]}$ in the JoinPathList
- From its adjacent List, locate the Table $T_{[k]}$ adjacent to it and do the following:
  - Locate the entry of $T_{[k]}$ in the JoinPathList
  - FindKey($B^+Tree(T_{[k]})$, $Keys_{[i]}$)
  - While found(keys[i]) do

    ReturnKeys($B^+Tree(T_{[k]})$, $keys_{[k]}$, $InheritedKeys_{[k]}$, [DP_k])

    Locate the entry of $T_{[ik]}$ in the JoinPathList

    From its adjacent List, locate the definition of the keys and inherited keys

    From $keys_{[i],}$ $inheritedkeys_{[i]}$, $keys_{[k],}$ $inheritedkeys_{[k]}$ get the keys and inherited keys of T[$_{ik]}$

    DelJoinKey ($T_{[ik]}$, $Keys_{[ik]}$, $InheritedKeys_{[ik]}$, [DP_{ik}])

    NextKey($B^+Tree(T_{[k]})$, $Keys_{[i]}$)

B⋈Tree with incremental Join

Due to the fact that join is commutative and associative and we are working on Virtual Tables and using indexes on them; it is possible instead of calculating all the join combinations to calculate incrementally the join.

This issue works just when the n tables are in direct path join between them but if they are not we are not interested.

Giving a casual order for the tables.

Beginning from Table 0, get a table T_i in direct join with it.

A Join Path List comes out with 2 entries from T_o to T_i and from T_i to T_0.

The index number start always with 0.

Repeat, with T_0 orT_i and get a next table that is in direct join with T_0 or with T_i, the process continue till we scan all the tables.

This algorithm is linear, is 2*n – 1.

Complexity of the algorithm for the creation of JoinPathList.

The complexity for the creation of JoinPathList structure is:
2*n-1 where n is the number of tables in join.

Proof:
We can prove it by induction on the number of tables in join.

For m = 1:

The complexity should be 2*1-1 = 1 in fact it is the only table that get inserted in the JoinPathList.

For m = n-1:

Suppose that the number of tables in JoinPathList is 2*(n-1)-1.

For m = n:

The n^{th} table get inserted as a Vertex in the JoinPathList at the beginning of the algorithm.

The n^{th} table get inserted in queue and path dynamic arays because the n tables are in join and at least there is one table in the (n-1) remaining table that is in join with the n^{th} table.

So when the algorithm run at certain point should execute:

$T_{[buf]}$ + = T_i

Insert NodesList[$T_{[buf]}$] = $T_{[buf]}$

where T_i is $T_{n,}$ so the number of tables in JoinPathList are: 2*(n-1)-1 + 1 + 1 = 2*n-1

Complexity of the algorithm for the insertion and deletion.

Delete is symmetric to insert in the algorithm in the sense where there is an insert we use a delete, so they have both the same complexity.

When inserting a new row in the database we use the B^{Join}Tree mechanism to drive us in the insert for the join.

Suppose that the order of the B^+Trees is m and the number of elements for every B^+Tree with i as index from the (2*n-1) B^+Trees is $p_i * l_i$ where in average there is l_i elements satisfying the join between every pair of tables.

In the worst case when get inserted row with the lowest order tables T_0 and T_1 in this case we call recursively the insert procedure for (2*n – 1) – (n - 1) = n times.

The complexity will be:

$Ord(n * \log_m(l_i * p_i))$

Complexity of the algorithm for the other operations.

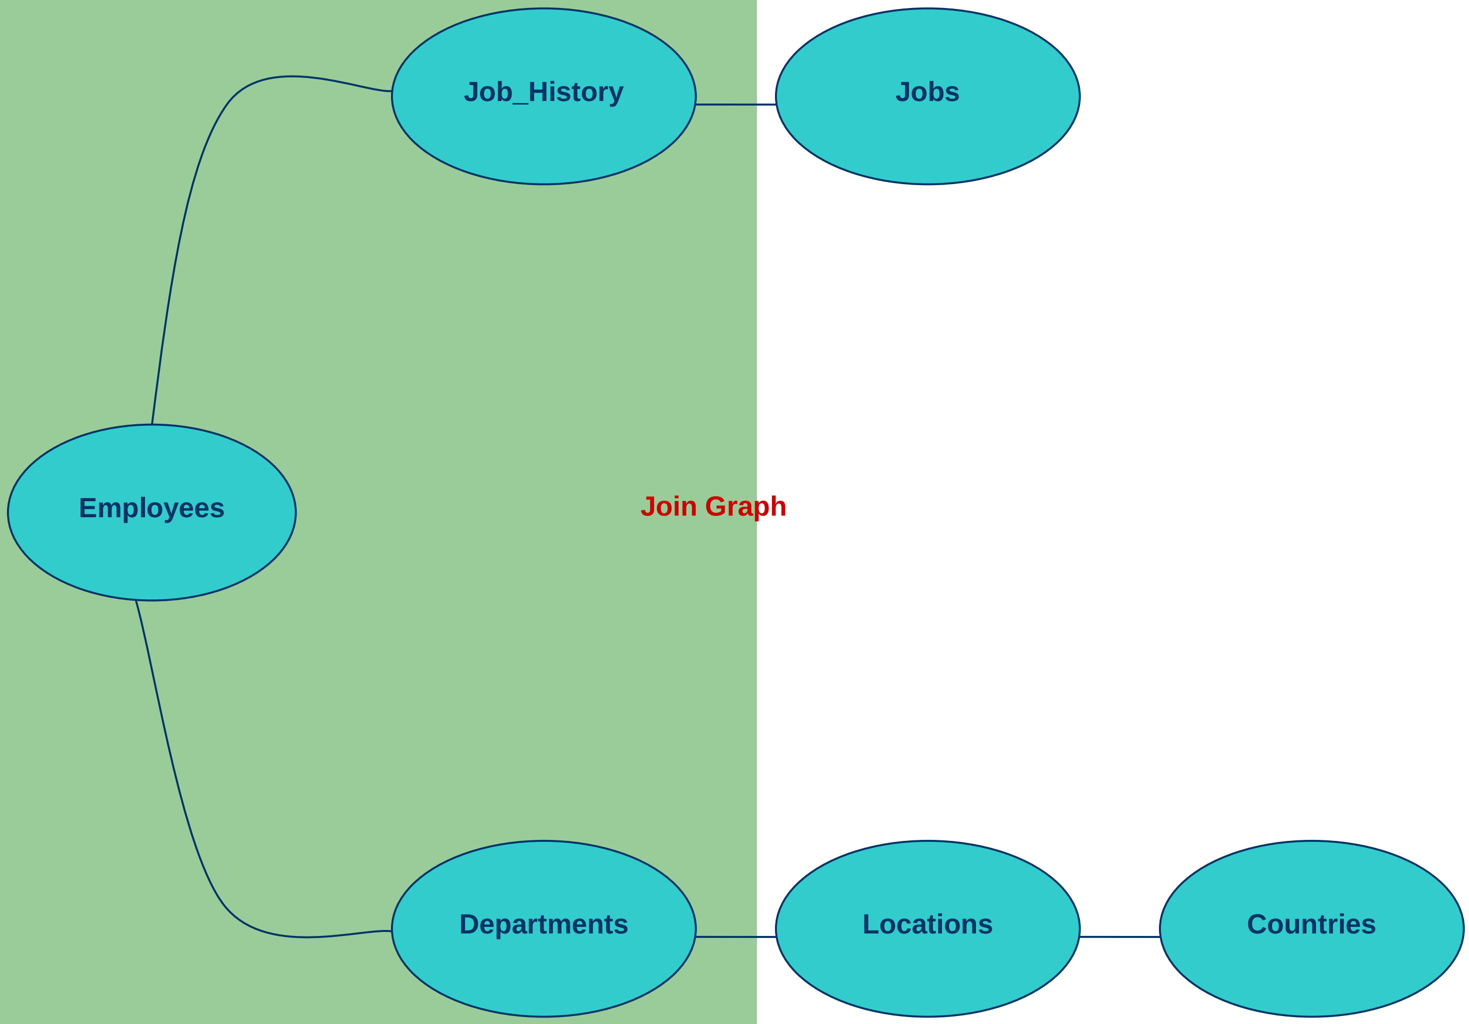
The only B^+Tree of our interest for the scan is the one with the latest index that have the join of the tables inside it.

Suppose that the number of elements for the latest index is $p_{(2*n-1)}$ so the other operations on this B^+Tree for find, search, prev, next,… are the same as for normal B^+Tree.with the same number of elements.

Proof of correctness.

To prove the correctness of the algorithm let see how does the algorithm work for the example above and later generalize it.

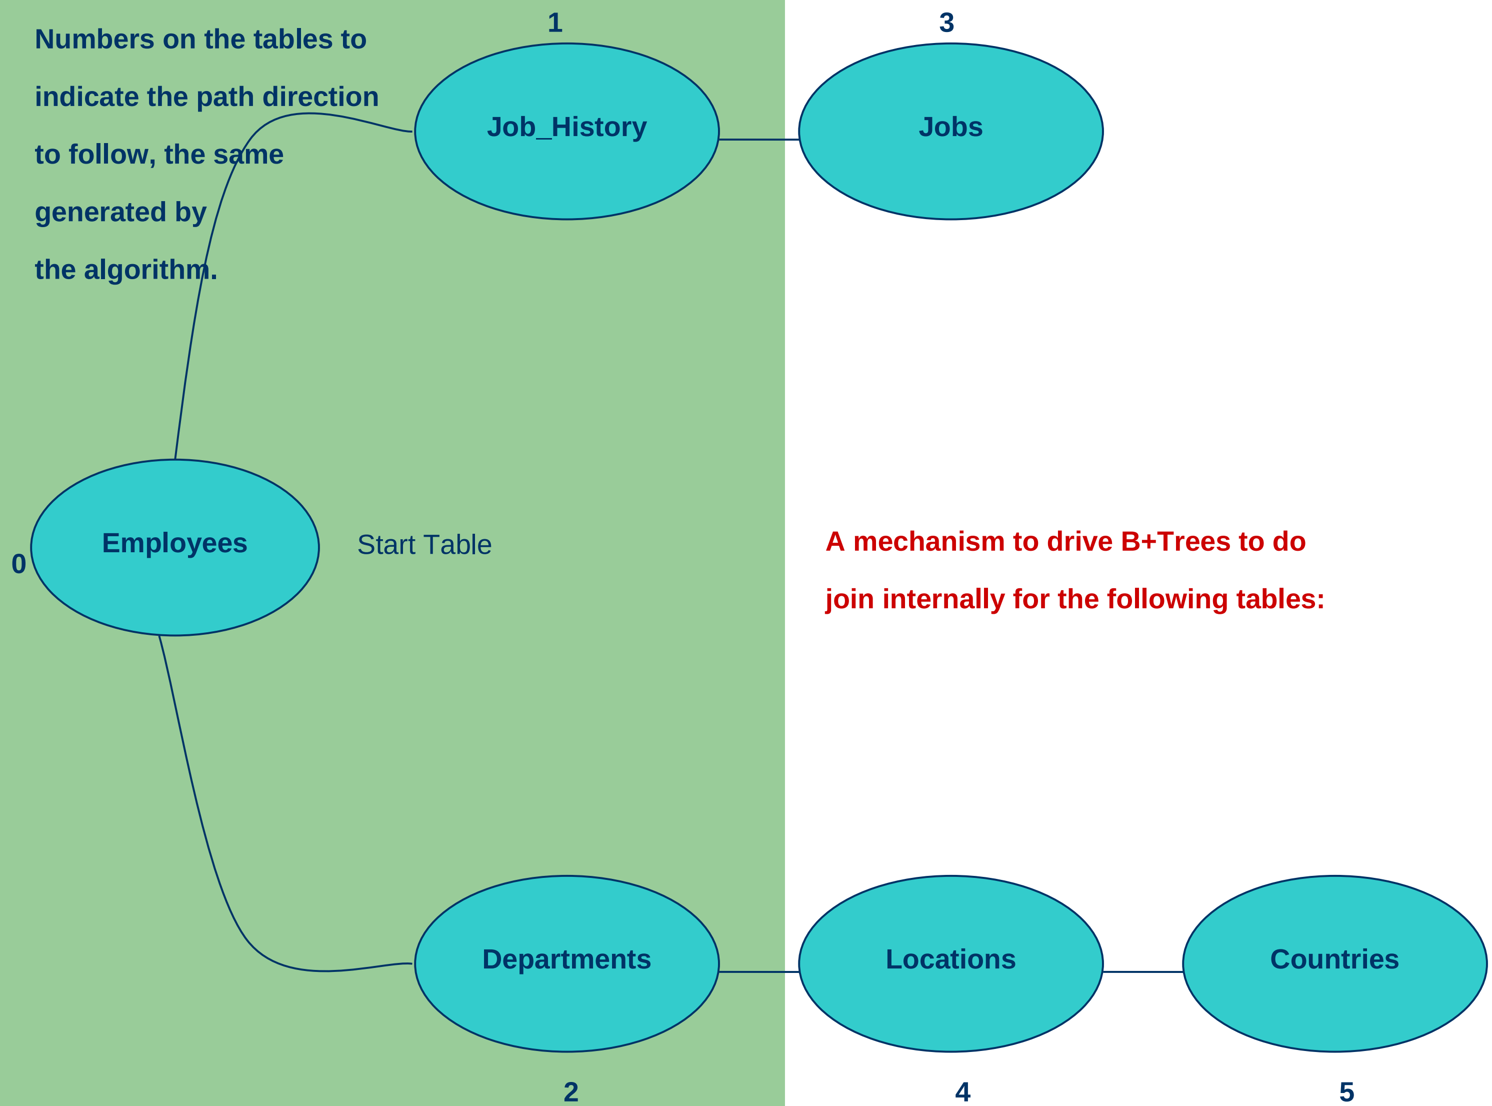
The Join Graph could be calculated easily even manually when we know which Tables are in direct join with others.



Let define a path in the Join Graph, the same path generated by the algorithm:

generateJoinPathList

Numbers on the tables to indicate the path direction to follow, the same generated by the algorithm.



A mechanism to drive B+Trees to do join internally for the following tables:

Notice that in the path if we reach one table it is not necessary to continue from it.

This is very important because this makes the tables free from any order,

independent selection of the start table.

By grouping comes out:`
Base Tables

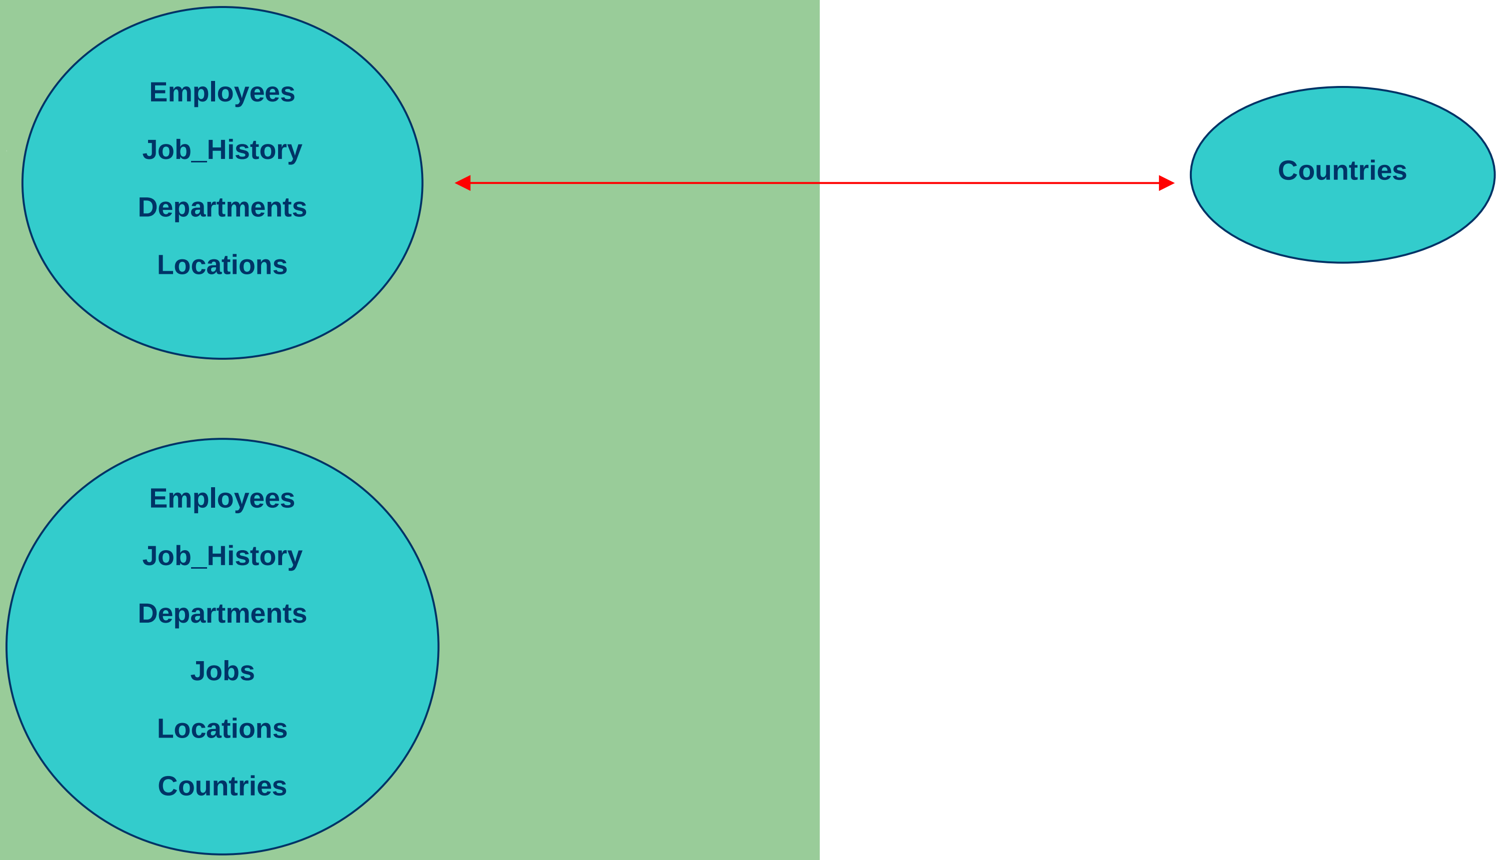
Locations



There is no restriction on how the rows from base tables get inserted (Any order with any sequence).

As we can see for every Virtual Table there is a Base Table in which there is a direct join between them and vice versa, in fact they belongs to the same Path in the Join Graph.

The idea consists in that every Virtual Table is constituted from Base Tables that are in join together. In fact the Base Tables constituting the Virtual Table appears by adding one at time that is in direct join with the one of the previous tables.

Now the join between tables should be calculated and stored to be found. For this reason B+Tree is declared for every Virtual Table that can hold references for rows from Base Tables constituting the Virtual Table in mode that concatenating them together bring out a joined Row.

Rows are inserted into a database as one row from a base table at a time, the system look for the link table, and check the B+Tree to see if there is any row that satisfy the join with the newly inserted; if this is the case combine each row satisfying with newly inserted by their references, and insert the combined row in the virtual table that has as base tables the base tables of the 2 previously tables.

So at any time when a row get inserted, the link table may eventually have the rows that satisfy the join with it, so they are combined and the process continue to the last virtual table or if they didn't get inserted yet in the virtual table, later when they get inserted they are confronted with the one inserted yet and the process continue on the same way.

The last table will contain all base tables in join together.

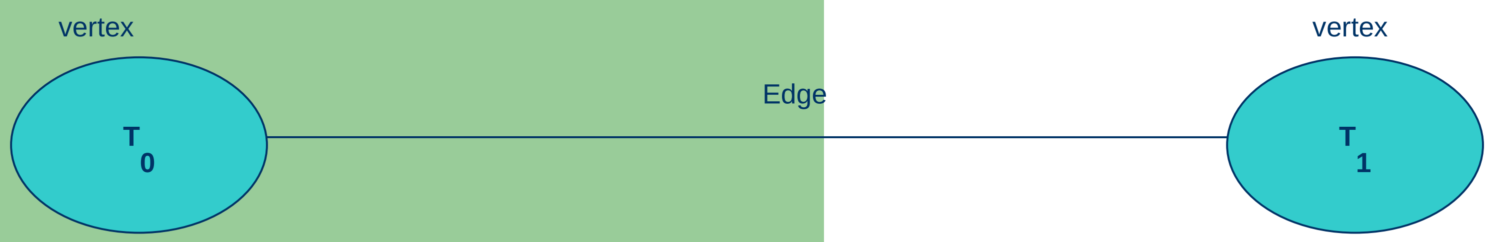
Proof of correctness.

Notice that what we show before is independent from the number of tables, so that the same reasoning apply to any number of tables and the proof of correctness could be easily proved by induction.

Let prove the correctness by induction.

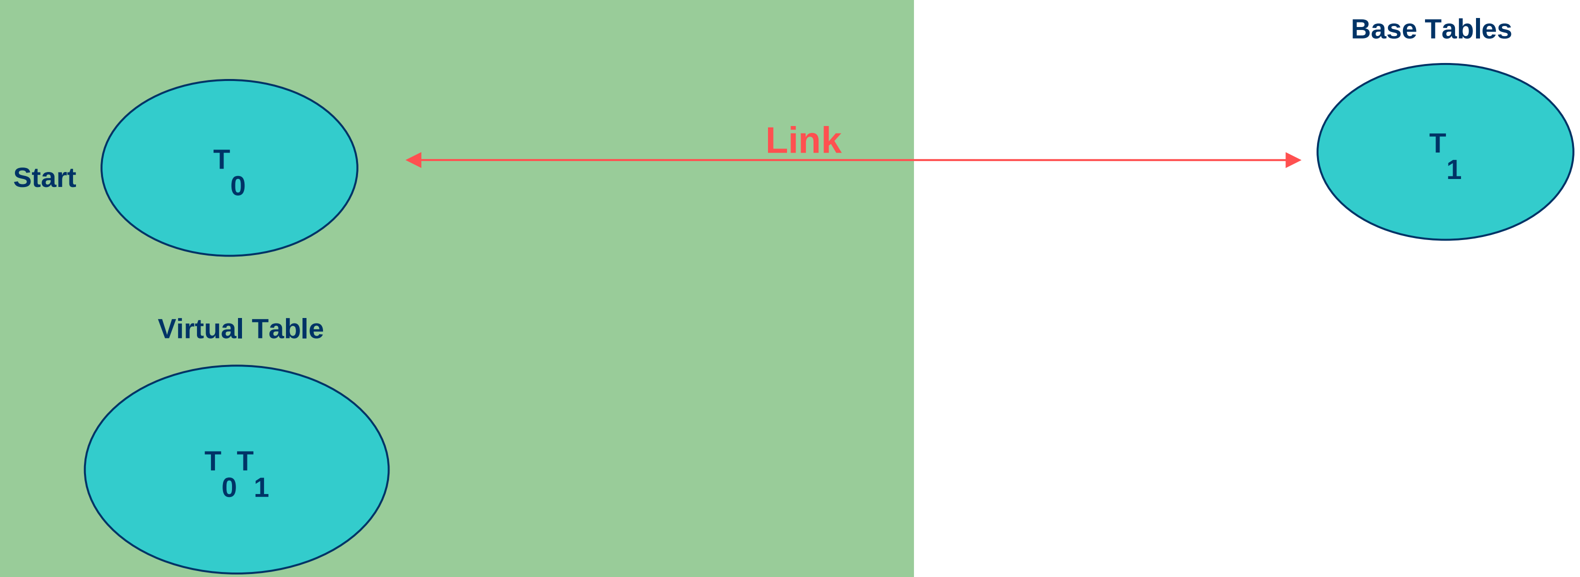
To do it, let see the correctness for 2 tables T_0 and T_1 in join together.

The join graph should be the following:

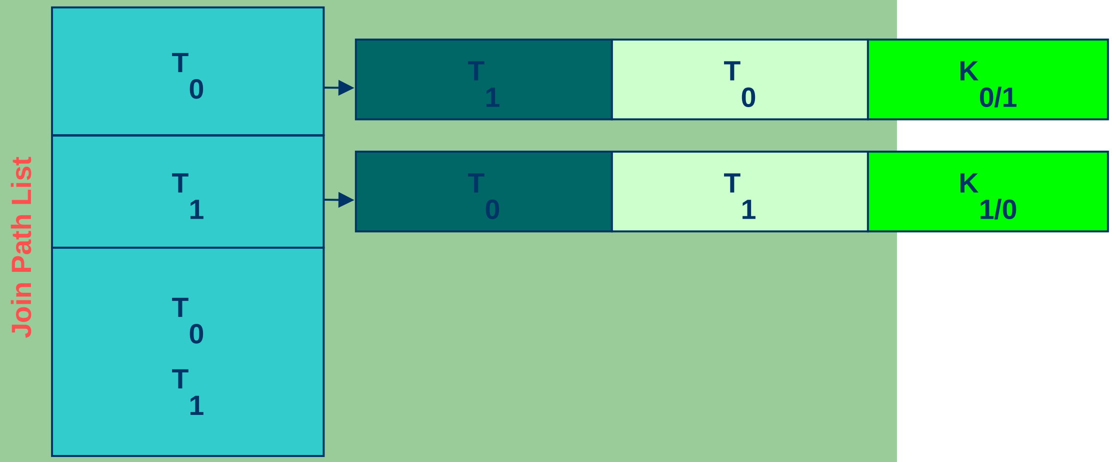


There are just 2 paths between the 2 tables: or from T_0 going toward T_1 or vice versa, let consider the former, the second case is symmetric and after all T_0 and T_1 are of arbitrarily choice.

By grouping comes out:



So, the JoinPathList should be the following:



If any key has been defined on the last virtual table and doesn't exist as a key on the base tables then should be propagated as inherited key in the appropriate base table; but for the prove of correctness in case of 2 tables, it is not important.

To prove the correctness of the algorithm, we have to prove that the last virtual table contain data references to all the rows that combined form the join between the 2 base tables and only those in other sense it is equivalent to the result of the join between the 2 tables.

Let prove that the last virtual table contain data references to all the rows that combined form the join between the 2 base tables:

Suppose by absurd that there is a row $R_{m/0}$ from table T_0 and a row $R_{n/1}$ from table T_1 that are in join together and they don't have references in the last virtual table.

If the 2 rows are in join together so their respective keys satisfy the join condition.

Suppose that $R_{m/0}$ comes first, so key($R_{m/0}$) is inserted in the B+Tree(T_0).

When $R_{n/1}$ get inserted later, the insert algorithm look in JoinPathList the adjacent table to T_1, it finds that T_0 is such table and look in B+Tree(T_0) all the keys that satisfy the join condition with the value of key($R_{n/1}$). It will get key($R_{m/0}$) because such key satisfy the join condition, it will combine the data references of the 2 Rows and insert in the virtual table such couple of references.

This is in contradiction on what we assume initially.

The case that $R_{n/1}$ comes first is symmetric.

Let prove that the only couples of data references in the last virtual table are those that combined make the join between the 2 base tables:

Suppose by absurd that there is a couple of references DP_0 and DP_1 that are data pointers to rows from table T_0 and table T_1 respectively in the virtual table and that the combined row doesn’t belong to a join between the 2 base tables.

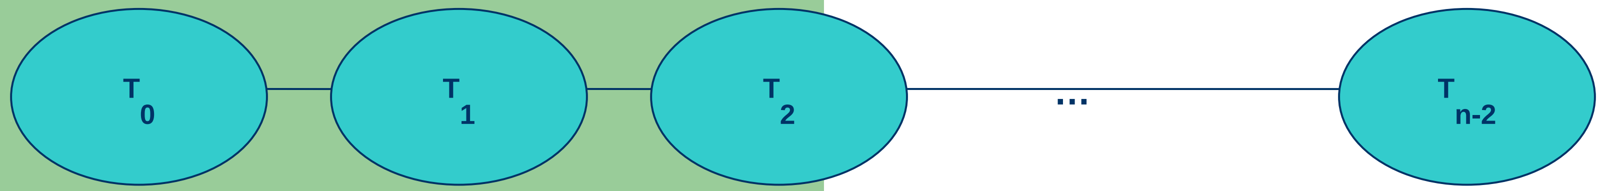
If such a couple of data pointers exist, it comes out because there is 2 keys belonging to the rows pointed by the data pointers and such keys satisfy the join condition, this is in contradiction on what we assume initially.

The initial case when there is only 2 tables in join is proved to be correct. Now let suppose that the correctness is true for n-1 tables and let prove it when the number of tables is n tables.

The easiest way to prove it for n tables is to expand the virtual table with (n-1) base tables. This virtual table has a B+Tree that is constituted from set of elements in which every element has a common key value with the nth table and (n-1) data pointers that points to the (n-1) base tables. By expanding in the sense that from every element taking the (n-1) rows from the (n-1) tables and considering them as one row in a virtual table, we can look at the virtual table as a table populated with such rows.

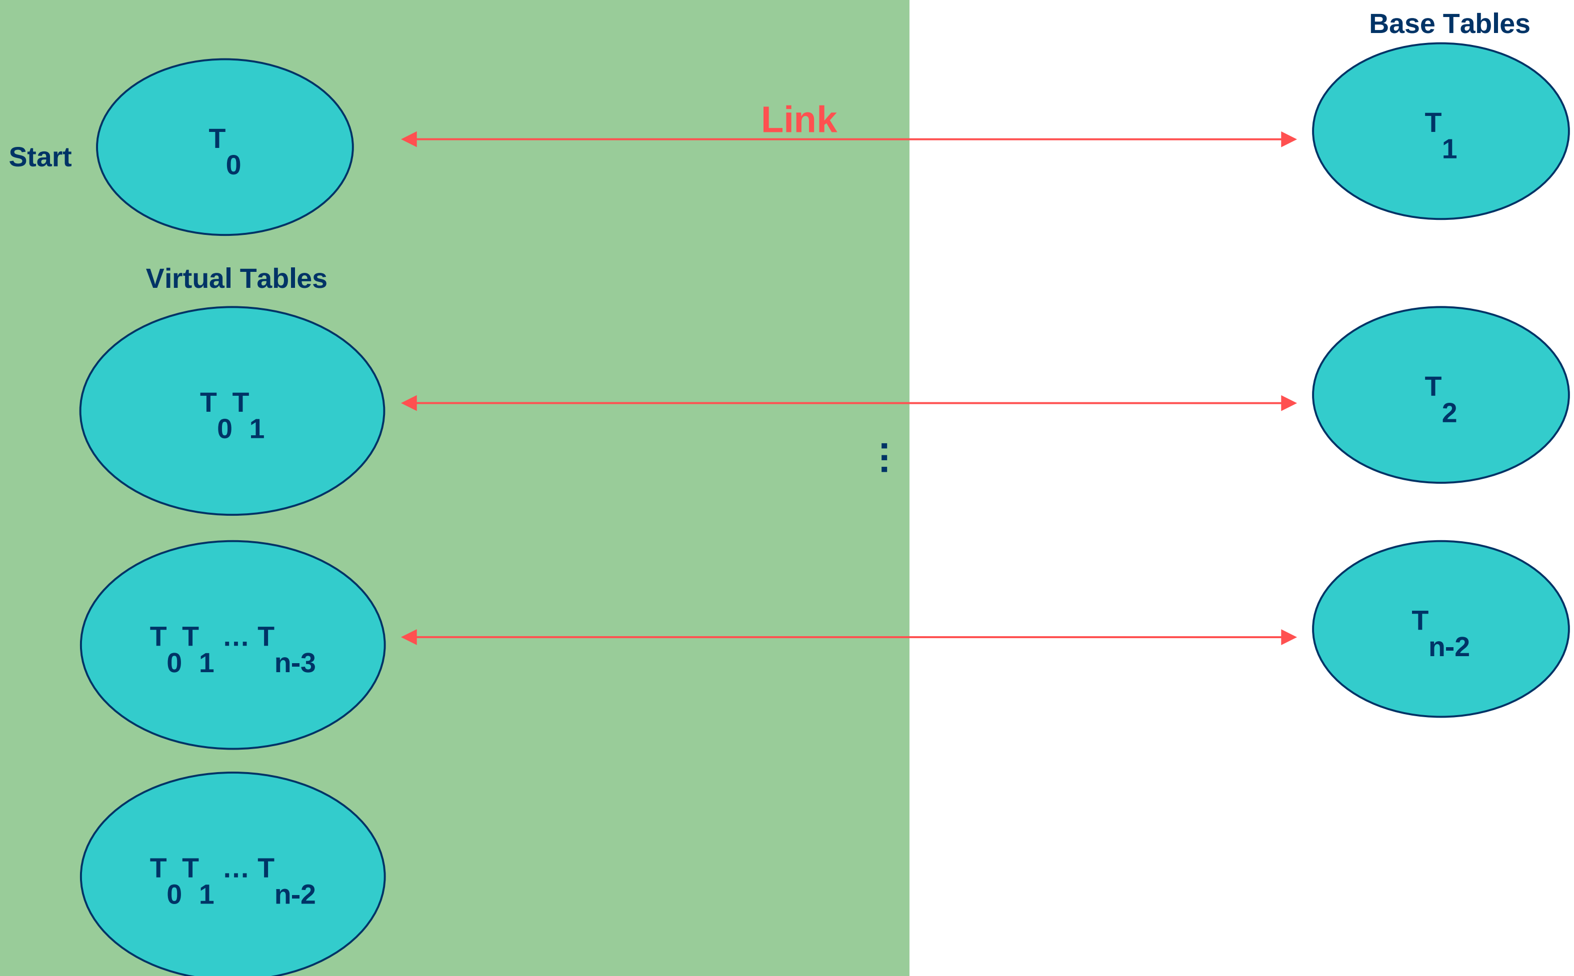
Let see first the Join Graph for the (n-1) tables and how they went in group and later what happens when we consider the nth table.

The join graph for the (n-1) tables should be the following:

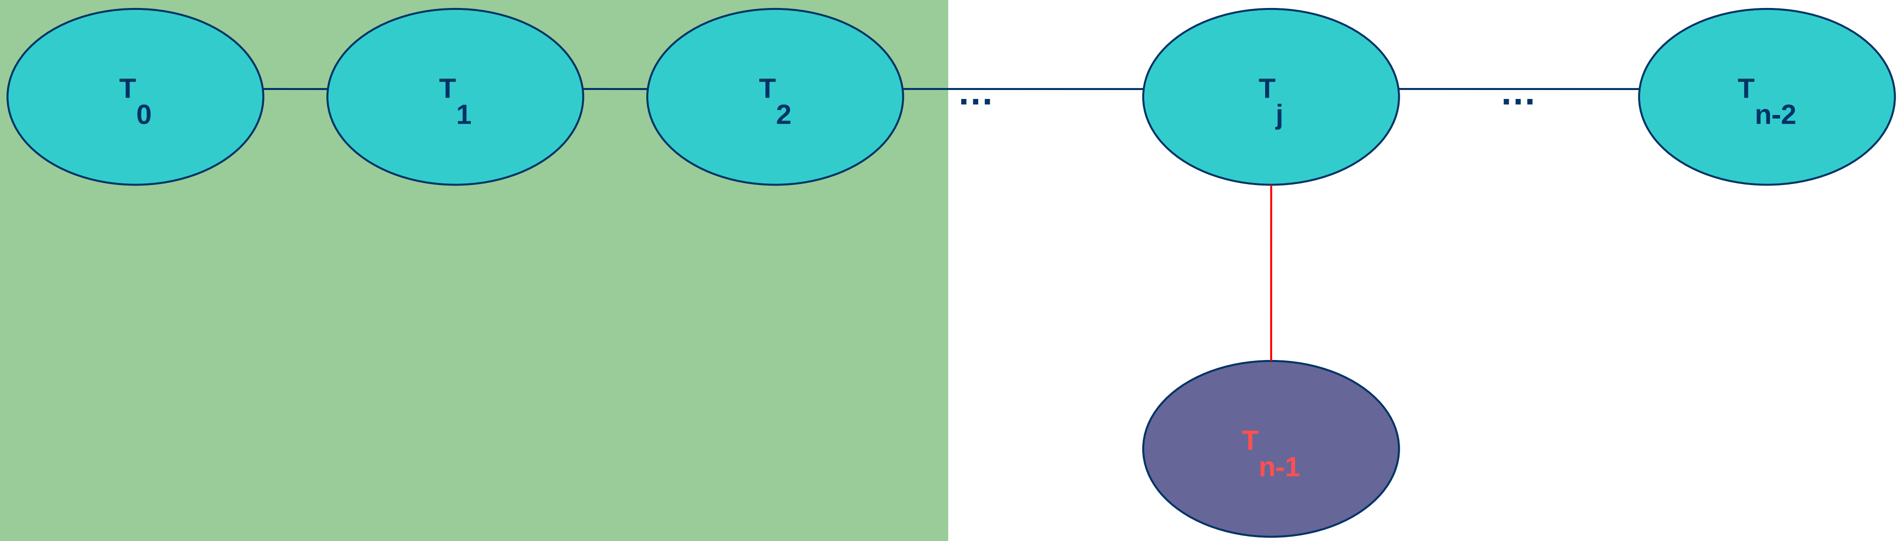


Suppose that the choice of $T_0 \dots T_{n-2}$ are in the way that the path start from T_0, continue by $T_1 \dots T_{n-3}$ till the end to arrive at T_{n-2}.

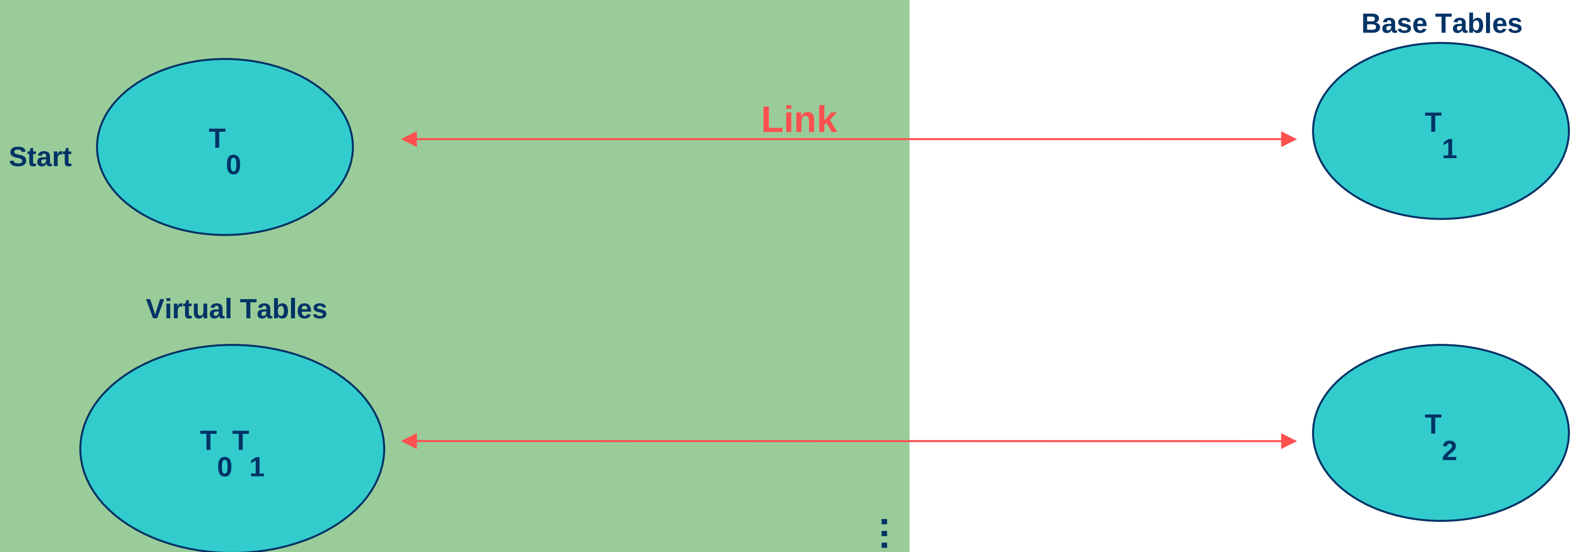
By grouping comes out:

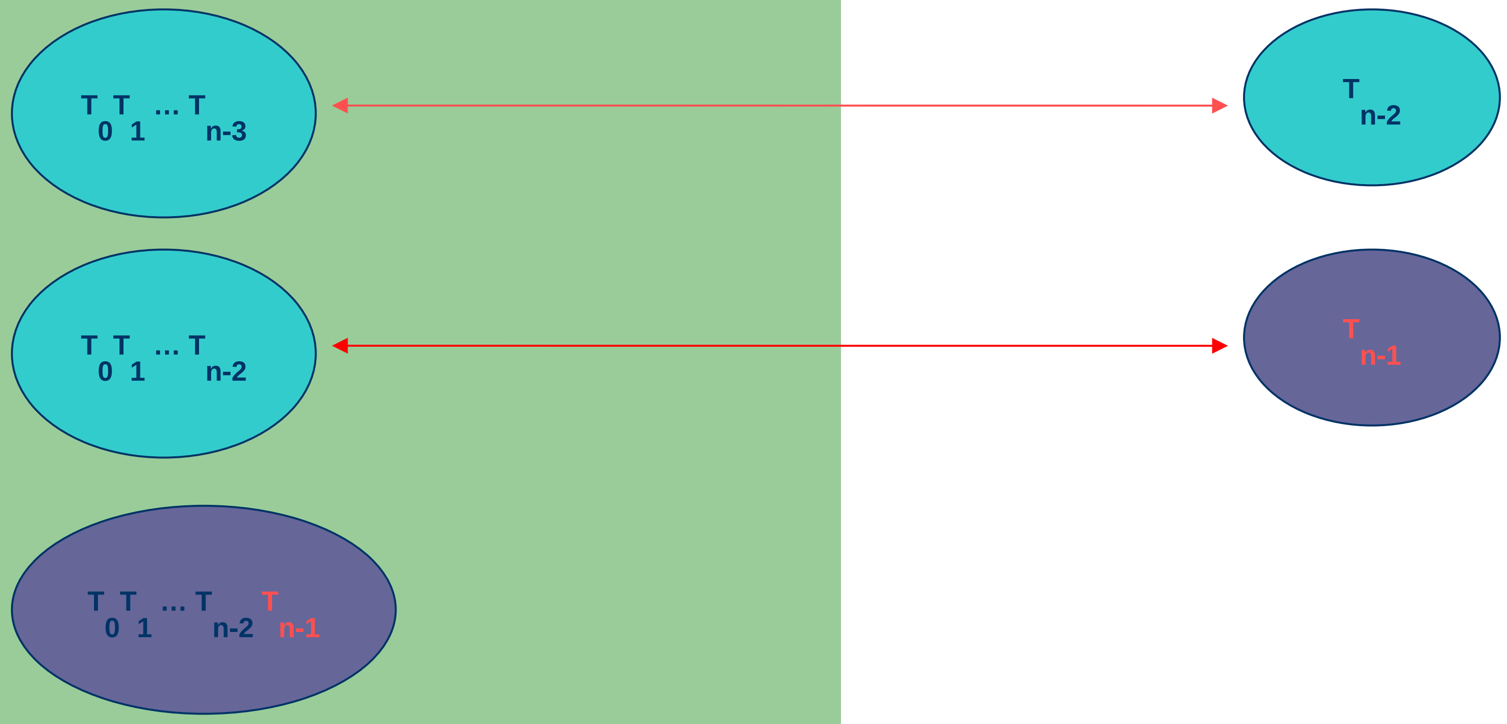


If there is one more table, the join graph would be the following:



The path should looks like this:





So if we expand the virtual table T_0 … T_{n-2} so the link would be just between it and the table T_{n-1}, where he common key should be from table T_j.

So we have the following situation:

Table T_0 …$_{n-2}$ an expanded table from the virtual table T_0 … T_{n-2} and by induction it is the same table obtained by the join of the (n-1) base tables.

Table T_{n-1}

So if we name T_0 …$_{n-2}$ as T_0 and T_{n-1} as T_1, we return to the case already proved of 2 tables where the common key in T_0 …$_{n-2}$ is calculated from the combined joined row in the place of the row pointed by DP_j.

The only thing remain to prove is the propagation of the key from $T_0 \ldots T_{n-2}$ to T_j and the eventual keys from $T_0 \ldots T_{n-1}$ to some base tables in the base tables $T_0 \ldots T_{n-1}$ but this is guaranteed in the third phase of the algorithm generateJoinPathList because it goes backward and insert eventual inherited keys.

Self Join

If the table is in join with itself, consider the table twice, every one with the necessary index.

Let see an example of self join.

Suppose that we add a column named SUPERVISOR_ID in the table EMPLOYEES, it has the id of the supervisor for a given employee.

Suppose that we have the following query:

```
SELECT A.EMPLOYEE_NAME, B.EMPLOYEE_NAME
FROM EMPLOYEES AS A, EMPLOYEES AS B
WHERE A.EMPLOYEE_ID = B.SUPERVISOR_ID
```

The table EMPLOYEES with the new column SUPERVISOR_ID is shown in slide 575.

generateJoinGraph (in BaseTables; out JoinGraph)

insert the base tables as vertexes of the graph
